The accessible information of general signal states is obtained by performing a generalized measurement. In the case that the signal alphabet consists of two states of a qubit system, it is proved that a von Neumann (orthogonal) measurement is sufficient to reach the accessible information.

PACS numbers: 03.67.Hk
Keywords: accessible information, POVM, von Neumann measurement

arXiv:0809.0232v1 [quant-ph] 1 Sep 2008

Mutual information is the fundamental quantity of information that two parties, Alice and Bob, share. Assume that Alice encodes a message by sending a specific quantum state ρ_r for each letter in the alphabet of the message. The rth letter in the alphabet occurs with probability $\mathrm{tr}(\rho_r)$ in the message. Bob sets up a measurement apparatus to determine which state was sent, described by an n-outcome positive operator valued measure (POVM) in a d-dimensional space, the range of $\sum_r \rho_r$,

$$\sum_{j=1}^{n} \Pi_j = \mathbf{I}_{d\times d},\ \Pi_j \geq 0\ \ \forall j \leq n. \tag{1}$$

This gives a joint probability matrix

$$p_{rj} = \mathrm{tr}\left(\rho_r \Pi_j\right) \tag{2}$$

which denotes the probability of Bob to receive outcome j and Alice to send l. We denote the marginals of the distribution by

$$p_{r\cdot} = \sum_j p_{rj},\ \ p_{\cdot j} = \sum_r p_{rj}. \tag{3}$$

The mutual information

$$I(\rho, \Pi) = \sum_{r,j} p_{rj} \log\left(\frac{p_{rj}}{p_{r\cdot} p_{\cdot j}}\right) \tag{4}$$

tells us how much information on average is transmitted to Bob per sent state [1]. Choosing a POVM that maximizes the mutual information defines an important quantity; this is called the accessible information

$$I_{\mathrm{acc}} = \max_{\Pi} I(\rho, \Pi). \tag{5}$$

The question which POVM maximizes the mutual information, which was raised by Holevo in 1973 [2], is generally unanswered and usually addressed numerically [3, 4, 5]. Even the simpler question of how many outcomes are sufficient is unanswered. It has been shown [6] that an orthogonal (von Neumann) measurement, i.e.

$$\Pi_l \Pi_k = \delta_{lk} \Pi_k,\ \ \mathrm{tr}\{\Pi_k\} = 1, \tag{6}$$

is in general not sufficient. Levitin [7] conjectured in 1995 that if Alice's alphabet consists of up to d states, an orthogonal measurement is sufficient. If so, the number of outcomes would be equal to the dimension of the Hilbert space. This conjecture has been shown not to hold in general by Shor [8]. In the same paper Shor reported that Fuchs and Perez affirmed numerically that if the alphabet consists of two states the optimal measurement is an orthogonal measurement. This is the *orthogonal measurement conjecture*. For two pure states it was proved to be true in arbitrary dimensions by Levitin [7].

This conjecture has important experimental and theoretical implications. In an experiment, orthogonal measurements are generally easier to implement than arbitrary generalized measurements. From a theoretical point, knowing the accessible information is crucial to determine the $C^{1,1}$-channel capacity [9] and for security analysis using the Csiszár-Körner theorem [10], for example the thresholds for a collective attack on the Singapore protocol [11] are obtained by determining the accessible information. Work has been done under the assumption that this conjecture is true [12]. In the sequel we will prove this conjecture for qubits.

Label the two states of the qubit system by ρ_1 and ρ_2. It is always possible to find a basis in which their matrix representation is real. Hence, we can conclude from Sasaki *et al.* [13] in an extension of the proof by Davies [14] that the maximum number of rank-1 outcomes needed to reach the accessible information is three. In the same paper Sasaki showed that these outcomes can be chosen to be real as well. The outcomes can be written $\Pi_j = |j\rangle\langle j|$ where in general $\langle j|\, j\rangle < 1$. What we will show in the following is that two of these vectors have to be linearly dependent if the mutual information is maximal. The most general variation of these outcomes is given by

$$\delta\,|j\rangle = i \sum_m |m\rangle \epsilon_{mj},\ \ \epsilon^*_{mj} = \epsilon_{jm} \tag{7}$$

with ϵ representing an arbitrary hermitian three by three matrix. With this variation, the first order variation of

the mutual information is given by

$$\begin{aligned}\delta I &= \sum_{r,j} \delta p_{rj} \log \frac{p_{rj}}{p_{\cdot j}} \\ &= -2 \sum_{r,j,m} \mathrm{Im}\left(\langle j| \rho_r |m\rangle \epsilon_{mj}\right) \log \frac{p_{rj}}{p_{\cdot j}}.\end{aligned}$$

For each pair of outcomes (k,l) we can set ϵ_{mj} for $\{k,l\} \neq \{m,j\}$ to zero, except for $\epsilon_{kl} = \frac{i}{2}$ and $\epsilon_{lk} = -\frac{i}{2}$. This gives us the following set of variations

$$\delta_{(k,l)} I = \sum_{r=1}^{2} \langle k| \rho_r |l\rangle \log\left(\frac{p_{rk}}{p_{rl}} \frac{p_{\cdot l}}{p_{\cdot k}}\right) = 0. \tag{8}$$

Since these sets are antisymmetric in k,l we get exactly three independent pairs. Fix one of the directions, say $|1\rangle$, and one vector $|0\rangle$ orthonormal to $|1\rangle$ to complete a basis of our real Hilbert space. Any vector $|n\rangle$ can be expressed as

$$|n\rangle = \beta_0(n)|0\rangle + \beta_1(n)|1\rangle. \tag{9}$$

We want to see what are the restrictions from these equations (8) on the vectors. When β_0 is zero the conjecture is trivially true, since the vector would be proportional to $|1\rangle$. Observe that, due to scale invariance of (8), it is always possible to divide out $\beta_0 \neq 0$ and restrict ourselves to $|n\rangle = |0\rangle + t|1\rangle$ with t an arbitrary real number.

In the following we assume neither ρ_1 nor ρ_2 to be pure. We will outline how to approach this case at the end of the paper. We get:

$$0 = \langle 1| (\rho_1 + \rho_2) |1\rangle \sum_{r=1}^{2} \alpha_r Q_r'(t) \log \frac{Q_r(t)}{\alpha_1 Q_1(t) + \alpha_2 Q_2(t)} \tag{10}$$

with

$$Q_r = t^2 + 2t \frac{\langle 1| \rho_r |0\rangle}{\langle 1| \rho_r |1\rangle} + \frac{\langle 0| \rho_r |0\rangle}{\langle 1| \rho_r |1\rangle}, \quad \alpha_r = \frac{\langle 1| \rho_r |1\rangle}{\langle 1| (\rho_1 + \rho_2) |1\rangle} \tag{11}$$

and *prime* denoting differentiation with respect to t. Introducing

$$\xi_r = \frac{\langle 1| \rho_r |0\rangle}{\langle 1| \rho_r |1\rangle}, \quad \eta_r = \frac{\langle 0| \rho_r |0\rangle}{\langle 1| \rho_r |1\rangle}, \tag{12}$$

the range for these variables is restricted due to positivity of the states to

$$0 \leq \xi_r^2 < \eta_r < \infty, \quad 0 < \alpha_r < 1, \quad r = 1,2, \quad \alpha_1 + \alpha_2 = 1. \tag{13}$$

The following theorem is the cornerstone for handling the general case:

Theorem 1. *Each function defined by*

$$f_{(\alpha,\xi,\eta)}(t) = \sum_{r=1}^{2} \alpha_r Q_r'(t) \log \frac{Q_r(t)}{\alpha_1 Q_1(t) + \alpha_2 Q_2(t)} \tag{14}$$

with constraints given by (13), $Q_r(t) = t^2 + 2t\xi_r + \eta_r$ and $Q_r'(t) = 2(t + \xi_r)$, has at most two real roots.

We will prove this later; first, we use this theorem to show our central result:

Theorem 2. *Every local maximum of the mutual information is a von Neumann measurement.*

Proof. Assume that the mutual information is stationary and that POVM is not von Neumann. Observe that in (14) if one logarithm is zero, automatically the other is zero as well. Since $|2\rangle$ and $|3\rangle$ have to be distinct, Theorem 1 tells us that one of these states must set the logarithm to zero, say $|3\rangle$. This means that

$$\frac{p_{\cdot 1} p_{13}}{p_{\cdot 3} p_{11}} = 1 \leftrightarrow \frac{p_{21}}{p_{11}} = \frac{p_{23}}{p_{13}},$$

so outcome 1 and outcome 3 are equivalent. Since the same reasoning is applicable to $\langle 2|$ instead of $\langle 1|$ in equations (8),(10) we find that all outcomes are equivalent and we are in a minimum. □

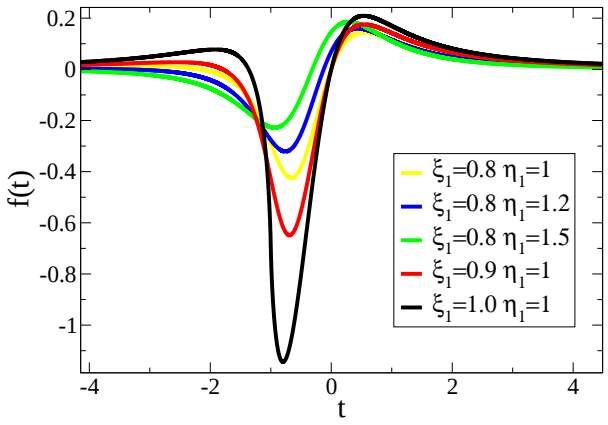

FIG. 1: Illustrating the function $f(t)$ in Theorem (1) for selected values, $\alpha_1 = \alpha_2 = 0.5$, $\xi_2 = 0$ and $\eta_2 = 1$, other parameters as stated in the graph.

The remainder of this paper will be used to show some lemmata to proof Theorem 1. The graph of f is plotted in Fig.1 for selected values of the parameters to illustrate its shape. Using Landau little-o notation and expansion of the logarithm in (14) shows that asymptotically

$$f(t) = 0 + o(1/t). \tag{15}$$

In particular, this implies that the function vanishes at infinity. Fortunately the term in front of the logarithm is linear, so by calculating the second derivative we arrive at a rational function. Introducing the abbreviations

$$L = Q_1' Q_2 - Q_2' Q_1, \quad Q_s = \alpha_1 Q_1 + \alpha_2 Q_2, \tag{16}$$

for the first and second derivative we get

$$\begin{aligned} f' &= 2\left(\sum_{l=1}^{2}\alpha_l \log\frac{Q_l}{Q_s}\right) + \alpha_1\alpha_2\frac{(Q_1'Q_2 - Q_2'Q_1)^2}{Q_sQ_1Q_2} \\ f'' &= \alpha_1\alpha_2\frac{L}{(Q_1Q_2Q_s)^2}P \end{aligned} \tag{17}$$

with

$$P = 3L'(Q_1Q_2Q_s) - (Q_1Q_2Q_s)'L. \tag{18}$$

The second derivative of f is a product of a rational function with a maximum of two zeros and no poles – since L is of second order and $Q_1Q_2Q_s$ strictly positive – and a sixth-order polynomial P. In the following we will show that the number of real roots of P is limited to two, which implies that the number of inflection points of f is limited by four. Since f approaches zero at infinity, it follows that the number of real roots of f is at maximum two, completing the proof of *Theorem 1.*

Since the number of roots is translation and scaling invariant, it is always possible to set $\xi_2 = 0$ and $\eta_2 = 1$. It will be convenient in the following to label ξ_1 simply as ξ and to introduce the difference between η_1 and ξ_1^2,

$$X = \eta_1 - \xi^2 > 0 \tag{19}$$

which is positive because of (13). Since a direct attack on this family of polynomials does not prove successful, we will look at its discriminant, showing that it is non-zero which implies that on the whole parameter domain no double root occurs. Since the coefficients (and therefore the roots) of our set of polynomials depend continuously on the parameters, any change in the number of roots occurs either by going through a double root or changing the degree of the polynomial. In particular we will use the following

Theorem 3. *Let G be a family of real valued polynomials with formal degree n, i.e.*

$$G : \mathbb{R}^m \to \mathbb{R}[x], z \mapsto G_z = \sum_{k=0}^{n} g(z)_k x^k$$

which is continuous in the coefficients of x, and D a connected domain of G for which the discriminant of G does not vanish. The number of roots of G_z is constant on each of the following domains

$$\begin{aligned} D_0 &= \{z \in \mathbb{R}^m | g(z)_n = 0\}, \\ D_1 &= D \backslash D_0, \end{aligned}$$

and the number of roots on D_1 is the number of roots on D_0 plus one.

Proof. Assume that the discriminant does not vanish. This implies that the polynomials on D_1 do not have any double root. Since the roots of the polynomials depend continuously on its coefficients this implies that the polynomials of each connected component of D_1 have the same number of real roots. The non-vanishing of the discriminant on D_0, where the highest coefficient vanishes, implies that the second highest coefficient is non-zero and that no double root occurs as well. This fixes the number of real roots on each connected component of D_0 as well, and there is exactly one less which went off to infinity. □

Corollary 1. *The discriminant $\Delta(P,t)$ of P is non-vanishing for all $\xi^2 > 0$ with $X > 0$ and $0 \le \alpha_1 \le 1$, and in the case that $\xi^2 = 0$ for all $0 < X \ne 1$ and $0 \le \alpha_1 \le 1$.*

Proof. The discriminant of P is given by

$$\begin{aligned} \Delta(P,t) &= 589824X\left[(1-X-\xi^2)^2 + 4\xi^2\right]^7 \\ &\quad \times \left\{-\left[\alpha_1(\alpha_2\xi^2+1) + \alpha_2 X\right]\right\} P_2(\alpha_1, X, \xi^2)^2 \end{aligned}$$

All terms except the last are obviously nonzero, so we take a closer look at the last term, which is a fourth order polynomial in X,

$$P_2(\alpha_1, X, \xi^2) = \sum_{k=0}^{4} Y_k(\alpha_1, \xi^2) X^k \tag{20}$$

We are now going to show that each of the coefficients is non-negative and at least one of them is non-vanishing, giving us a positive polynomial. The coefficient

$$Y_4 = \alpha_2^2(16\,\alpha_2 + \alpha_1^2) \tag{21}$$

is obviously zero for $\alpha_1 = 1$, since $\alpha_2 = 1 - \alpha_1$, and positive otherwise. The coefficient

$$\begin{aligned} Y_3 &= -4(\alpha_2)^2(3\alpha_1^2 + 4\alpha_1 - 8)\xi^2 \\ &\quad +4\,\alpha_2\left(-3\alpha_1^3 + 67\alpha_1^2 - 196\alpha_1 + 136\right) \end{aligned}$$

is affine in ξ^2. To show that this coefficient is greater than zero, we use that

$$-3\alpha_1^2 - 4\alpha_1 + 8 \ge -3\cdot 1^2 - 4 + 8 = 1$$

and

$$\begin{aligned} -3\alpha_1^3 + 67\alpha_1^2 - 196\alpha_1 + 136 &> -3 + 66\alpha_1^2 - 198\alpha_1 + 136 \\ &= 66(\alpha_1^2 - 3\alpha_1 + 2) + 1 = 66(2-\alpha_1)(1-\alpha_1) \ge 1 \end{aligned}$$

we have

$$Y_3 \ge 4\,\alpha_2\,(\alpha_2\xi^2 + 1) \ge 0$$

with $Y_3 = 0$ only if $\alpha = 1$. The remaining coefficient can be treated in a similar fashion so we will just state them for completeness.

Coefficient Y_2: Y_2 is a quadratic polynomial in ξ^2 :

$$\begin{aligned} Y_2 &= 2(-13\alpha_1^4 + 34\alpha_1^3 - 21\alpha_1^2 - 8\alpha_1 + 8)\xi^4 \\ &- 2(122\alpha_1^4 - 636\alpha_1^3 + 914\alpha_1^2 - 384\alpha_1 - 16)\xi^2 \\ &- 2\left(13\alpha_1^4 - 26\alpha_1^3 + 405\alpha_1^2 - 392\alpha_1 - 8\right) \end{aligned}$$

in which all terms can be shown to be non-negative.

Coefficient Y_0: The last term is given by

$$\begin{aligned} &Y_0 = \alpha_1^2(1+\xi^2)^2 \\ &\times \left[\xi^4(\alpha_2)^2 + \xi^2\, 2(1 - \alpha_1^2 + 6\,\alpha_1\alpha_2) + 1 + \alpha_1^2 + 14\alpha_1\right] \\ &\geq 0 \end{aligned}$$

This shows that the discriminant is non-zero. □

To determine the number of roots we need to look at one polynomial for conveniently chosen parameters. Choose

$$\xi = 2, \quad X = 1, \quad \alpha = \frac{1}{2}$$

giving us for (18)

$$P = -64(1+t)(7 + 8t + 8t^2 + 4t^3 + t^4)$$

which has exactly one real root. This completes the proof for mixed states. In the case that one of the states is pure, i.e. $\xi^2 = \eta$, the orthogonal measurement conjecture follows from continuity in all variables of the mutual information. To show the stronger statement of Theorem 2 one has to perform a similar analysis as the one done in this paper, with the difference, that the second derivative (17) has a maximum of three roots and one simple pole.

In this paper we proved the orthogonal measurement conjecture for general two qubit states. It is natural to ask if this proof can be extended to higher dimensions. Already for qutrits we are facing serious difficulties. Two qutrits can in general not be transformed to real matrices with only one unitary transformation. Restricting ourselves to real qutrit or qunit matrices we can derive equations of similar type as equations (8). Performing a similar expansions of the vectors in a basis as in (9) does not give us, as in this paper, functions of one real variable but gives rise to intersections of transcendental curves in projective space, leading us into a vast, unexplored territory.

I want to thank Berge Englert, Lai Choy Heng, Frederick Willeboordse, Jun Suzuki and Alexander Shapeev for valuable discussions and for making this work possible. This work is supported by the National Research Foundation & Ministry of Education, Singapore.
